Transporting and relocating dogs is an increasingly common practice. Whether the situation is an owned pet accompanying emigrating or traveling caretakers, the relocation of homeless animals for adoption, or the movement of dogs for competition, exhibition, research or sale, this process carries the risk of spreading infectious diseases. This includes the transmission of *Dirofilaria immitis* when infected dogs have become microfilaremic.

The following practices will minimize the risk of heartworm transmission associated with the transportation and relocation of dogs (see Algorithm, next page):

1. **Test all dogs greater than 6 months of age** for microfilariae (Mf) and heartworm antigen (Ag) prior to relocation.
   a. If testing is not possible, assume transmission is possible and proceed to Step 3b.

2. **If dogs test positive** for microfilariae or antigen, reconsider relocation at this time and begin treatment in accordance with the American Heartworm Society (AHS) Guidelines.
   a. Dogs with clinical signs attributed to heartworm infection should not be transported.
   b. Dogs that have been treated with melarsamine dihydrochloride should not be transported for at least 4 weeks after an injection to minimize stress and physical exertion that accompany the relocation process.
   
3. **If dogs test positive and relocation cannot be postponed**, clinical decisions should be based on the dog’s heartworm status.
   a. If Mf-, Ag+:
      i. Administer an approved macrocyclic lactone product. This should prevent the pre-patent dog from becoming microfilaria positive.  
      ii. Begin doxycycline therapy. A 4-week course of doxycycline should prevent the pre-patent dog from becoming microfilaria positive.  
      iii. Repeat Knott’s testing in 7 days; if negative, proceed with relocation. If positive, repeat Knott’s testing in 7 days. Two negative tests 7 days apart can provide reasonable assurance of a lack of circulating microfilariae and reduced risk of transmission.
   b. If Mf+, Ag- or Mf+, Ag+:
      i. Apply an approved moxidectin topical product and proceed with relocation. A single dose of topical moxidectin prior to transport will eliminate most microfilariae.  
      OR
      ii. Administer an approved macrocyclic lactone product along with a topical canine insecticide (containing permethrin + dinotefuran + pyriproxyfen) that is labelled to kill and repel mosquitoes. This will prevent infection of mosquitoes and subsequent transmission of infective larvae during transportation and for 1 month thereafter.
      iii. Begin doxycycline therapy. Administration of a 4-week course of doxycycline will render microfilariae incapable of normal development to infective larvae in mosquitoes and subsequent development of these larvae in dogs.

4. **If dogs test negative** for microfilariae and antigen, proceed with relocation.
   a. Administer macrocyclic lactone preventive drugs to dogs greater than 6 weeks of age prior to relocation.
   b. Repeat microfilariae and antigen testing in 6 months. If a history of preventive administration is well-documented, repeat testing in 12 months.

Caring for dogs that undergo relocation is an everyday challenge veterinarians face in today’s mobile society, and one that necessitates the adoption of approaches to mitigate heartworm transmission. Along with considering the recommendations in this document, veterinarians should ensure that transportation of animals is carried out in accordance with state and/or federal transportation regulations, as well as professional guidelines. In the case of organized homeless animal relocation programs, veterinarians should work with both source and destination organizations to establish protocols for minimizing transmission of infectious diseases, including heartworm disease.
